UPPER GASTROINTESTINAL BLEEDING: 
IS ONLY AN INJECTION OF EPINEPHRINE SUFFICIENT?
SUCCES RATES BY FORREST CLASSIFICATION

Abstracts: Objective: Endoscopic treatment is an effective and successful treatment for non-variceal upper gastrointestinal system (GIS) bleedings. In recent years, endoscopic combined therapies have been recommended for hemostasis. The aim of this study was to investigate primary hemostasis rates and re-bleeding rates obtained by epinephrine injection alone.

Material and Methods: We analysed patients who had alone endoscopic epinephrine injection treatment for upper gastrointestinal system bleeding between January 2014 and January 2019. Gender, age, etiology of bleeding, Forrest classification, treatment efficacy and re-bleeding rates of the patients were recorded. The files of the patients were analyzed retrospectively. Results: The number of patients who met the study criteria was 107. There were 16 patients in Group 1 (Forrest 1a), 64 patients in Group 2 (Forrest 1b) and 27 patients in Group 3 (Forrest 2a). Primary hemostasis was achieved in 14 (87.5%) of 16 patients in Group 1, 62 (97%) of 64 in Group 2, and 27 (100%) of 27 Group 3. Re-bleeding rates were 4 (28%), 10 (16%), 2 (7%) in groups 1,2 and 3, respectively.

Conclusion: It is thought that endoscopic combined treatment should be applied especially in patients with Forrest 1a and 1b bleeding ulcers, whereas in Forrest 2a ulcer patients, because of both the high rate of primary hemostasis and low rate of re-bleeding according to the results of the present study, the treatment of adrenal injection alone can be used alone like other hemostasis modalities.

Key words: Endoscopic treatment, Forrest classification, upper gastrointestinal bleeding.

INTRODUCTION

Upper gastrointestinal system bleeding has an incidence ranging from 48 to 160 cases per 100.000 people, depending on geographical regions. It is more common in men and in the elderly population. Different incidences between populations can be explained by various reasons such as drug-induced ulcers and the prevalence of Helicobacter Pylori (1, 2).

The peptic gastroduodenal ulcer is the most common cause of non-variceal upper gastrointestinal bleeding. Mallory-Weiss Syndrome, vascular abnormalities, iatrogenic bleedings after endoscopic procedures and bleedings at the surgical site can be given as other causes (3). Mortality due to upper gastrointestinal bleeding is associated with advanced age and accompanying comorbidities. The risk of mortality increases with recurrent bleeding (4). Despite the use of therapeutic endoscopy and gastric acid suppressors for optimal treatment, it is seen that the mortality rate has remained constant between 6% and 14% in recent years (5).

Endoscopic treatment is an effective and successful treatment for non-variceal upper gastrointestinal system (GIS) bleedings (6). Endoscopic treatment can significantly reduce the risk of bleeding or ongoing bleeding, the need for surgery, the number of packed erythrocyte units required for transfusion, and the length of hospital stay (6, 7).

Endoscopic hemostasis can be achieved using injection, and thermal and mechanical methods. Epinephrine, sclerosing agents (ethanol, ethanolamine, polidocanol) and thrombin/fibrin glue can be used in the treatment of injection (8, 9, 10).

AIM

The present study aims to investigate the primary hemostasis success rates and re-bleeding rates of upper gastrointestinal system bleedings, which are stopped by epinephrine injection alone as an endoscopic
treatment, according to the Forrest classification sub-groups.

**MATERIAL AND METHOD**

Patients who had endoscopic epinephrine injection treatment for upper gastrointestinal system bleeding between January 2014 and January 2019 in the general surgical endoscopy unit of Başkörköy Dr. Sadi Konuk Training and Research Hospital and had an endoscopic bleeding index of Forrest 1a, 1b and 2a were included in this study. The files of the patients were analyzed retrospectively. Gender, age, etiology of bleeding, treatment efficacy and re-bleeding rates of the patients were recorded. The Forrest classification was used as an endoscopic bleeding index (Table 1). Patients were divided into three groups according to the Forrest classification. Patients in Group 1 were classified as those having Forrest 1a, patients in Group 2 as those having Forrest 1b, and patients in Group 3 as those having Forrest 2a endoscopic bleeding index. Primary hemostasis success and re-bleeding rates of endoscopic injection treatment according to Forrest classification were reviewed. Hemodynamic deterioration, active hematochezia and a decrease of 2 g/dl or more in hemoglobin values within 24 hours during the follow-up of the patients who were provided hemostasis with the first endoscopic treatment were evaluated as re-bleeding and it was determined that the endoscopic procedure was repeated. Epinephrine of 1/10000 was used as the injection treatment. Those with 2b, 2c, and 3 endoscopic bleeding indexes according to Forrest classification, those using oral anticoagulants, those who have non-peptic ulcer bleeding causes in the etiology, and those with marginal ulcer and malignancy in gastrojejunostomy anastomosis were excluded from the study.

All procedures performed in this study, involving human participants were in accordance with the 1964 Helsinki declaration and its latest amendments or comparable ethical standards. Informed consent was obtained from all individual participants of the study.

**RESULTS**

It was seen that 536 patients underwent endoscopy for upper gastrointestinal bleeding in the endoscopy unit between 2014 and 2019. In 414 (77%) of these patients, gastroduodenal ulcer (49% duodenal ulcer, 28% gastric ulcer) bleeding was detected. The number of patients who met the study criteria was 107. There were 16 patients in Group 1 (Forrest 1a), 64 patients in Group 2 (Forrest 1b) and 27 patients in Group 3 (Forrest 2a).

When the etiology of bleeding was examined, 5 patients had gastric ulcer and 11 patients had duodenal ulcer bleeding in Group 1, 9 patients had gastric ulcer and 55 patients had duodenal ulcer bleeding in Group 2, and 4 patients had gastric ulcer and 23 patients had duodenal ulcer bleeding in Group 3 (Table 3).

When the treatment success rates were examined, it was seen that primary hemostasis was achieved in 14 (87.5%) of 16 patients but endoscopic hemostasis could not be achieved in 2 (12.5%) patients in Group 1. In the Group 2, however, primary hemostasis was achieved in 62 (97%) patients but endoscopic hemostasis could not be achieved in 2 (3%) patients. Four patients for whom primary hemostasis could not be achieved were operated. In Group 3, primary hemostasis was achieved in all 27 patients and the success rate was 100%. Primary hemostasis was achieved in 103 (96.2%) of 107 patients in all three groups. In Group 3, primary hemostasis was achieved in all 27 patients and the success rate was 100% (Table 4).

When examining the general results of the patients included in the study, it was found that a total of 6 (7.5%) of the 80 patients in Forrest 1a and 1b groups with bleeding ulcer were operated after their first and repeated endoscopy applications. In repeat endoscopy procedures, 1 patient underwent clips and 1 patient underwent argon coagulation, while 72 patients were treated endoscopically with epinephrine injection alone. Of these 72 patients, 10 had endoscopic epinephrine injection treatment on endoscopies for a second time, leading to hemostasis, and 62 (77.5%) had no need for a second procedure after primary hemostasis. None of the patients with visible vessels in the Forrest 2a group required surgery, and only 2 (7.5%) patients underwent repeated injections.

### DISCUSSION

The most common cause of non-variceal acute upper gastrointestinal system bleeding is peptic ulcer bleeding, which is observed between the rates of 28% and 59%. Duodenal ulcer rate is seen between 17% and 37% and gastric ulcer rate is between 11% and 24% (11). In the present study, the rate of peptic ulcer (49% duodenal ulcer, 28% gastric ulcer) was 77% (414/536) in endoscopies performed due to GIS bleeding and this result was higher when compared with the studies in the literature.

Studies have shown that endoscopic treatments improve clinical outcomes in GIS bleeding. Endoscopic treatment, especially in patients with high-risk bleeding lesions, significantly reduces the frequency of recurrence bleeding, the need for surgical intervention, and mortality (6, 12, 13).

Considering the timing of endoscopy, it has been reported that emergency endoscopy performed within 24 hours reduces the risk of mortality and surgical intervention in patients with high-risk upper gastrointestinal system bleeding. However, in many studies, there was no significant difference between patients who un-

derwent endoscopy within the first 24 hours and within the first 12 hours. Therefore, emergency endoscopy is recommended for patients suspected of upper gastrointestinal bleeding within the first 24 hours (14-17). In the present study, it was found that 96% (102/107) of the patients underwent endoscopy within 24 hours after admission.

Endoscopic hemostasis can be achieved by injection, and by thermal and mechanical methods. Epinephrine injection can be carried out with the applications of sclerosing agents, thrombin/fibrin glue applications, thermal contact (Heater probe thermoagulation) and non-contact (Argon plasma coagulation) devices and mechanical clip application. Epinephrine injection provides vasoconstriction while sclerosing agents help to achieve hemostasis by providing thrombosis (9, 11, 18).

Forrest classification was developed more than 40 years ago to standardize gastroduodenal ulcer bleedings. This classification has been used in numerous studies aimed at identifying patients at risk of persistent ulcer bleeding, re-bleeding, and death. Most of these studies have shown that the presence of ulcers classified endoscopically as F1a or F1b is an independent risk factor for permanent bleeding or re-bleeding (11, 19, 20). In the literature, the rates of rebleeding was reported vary between 90% for a Forrest Ia lesion and 5% for a Forrest III lesion (21).

In the literature, it is stated that hemostasis is achieved in the rates of over 90% with endoscopy in non-variceal upper gastrointestinal bleeding cases (22). In a study by Park et al., hemostasis rate achieved only by epinephrine injection was 97.7% in patients with bleeding ulcers, and hemostasis success rate achieved by combined treatment with epinephrine injection + mechanical clip was 97.7%, and no difference was found between these rates (23). In a study by Guagliemi et al., in patients with Forrest 1a, 1b, 2a and 2b ulcers, the primary hemostasis rate by epinephrine and sclerosing agent injection with endoscopy was reported to be 95.6% (20). In the present study, primary hemostasis rates were 87.5% (14/16) in Forrest 1a and 97% (62/64) in Forrest 1b. In Forrest 2a, however, 100% hemostasis was achieved, and the overall primary hemostasis success rate was 96.2% (103/107) in all three groups. Comparing these rates with both non-epinephrine injection monotherapy treatment modalities and combined treatment modalities, results like those in the literature were found in terms of ensuring primary hemostasis.

In non-variceal upper GIS bleedings, the rate of re-bleeding after endoscopic treatment has been reported to be approximately 24% in the literature (24). In randomized studies, initial hemostasis rates were at approximately 90% with endoscopic monotherapy treatments without taking the hemostatic method into account, and re-bleeding rates were reported to be between 2% and 10% in endoscopic monotherapies other than epinephrine injection. There was no significant difference between monotherapies in ensuring initial hemostasis. Although epinephrine injection is effective in ensuring initial hemostasis in patients with active ulcer bleeding, the rate of re-bleeding has been reported to be between 12% and 30% (25-28).

In a study by Park et al., the rate of re-bleeding in patients with Forrest 1a, 1b, and 2a ulcers was found to be 20.4% (9/44) in the group where hemostasis was achieved only by epinephrine injection. In the combined treatment group, however, this rate was found to be 4.5% (2/44) (23). In another study by Pescatore et al., re-bleeding rates were 57% for Forrest 1a, 24% for Forrest 1b, and 21% for Forrest 2a in patients with GIS bleeding for whom hemostasis was achieved epinephrine alone, while the re-bleeding rates were reported as 25% for Forrest 1a, 14% for Forrest 1b and 25% for Forrest 2a for the combined treatment of epinephrine + fibrin glue. In this study, the combined treatment significantly reduced re-bleeding rates in Forrest 1a and 1b ulcers but did not achieve a decrease in re-bleeding rate in Forrest 2a (28).

In a prospective randomized study by Chu-Lo et al., patients receiving epinephrine injection alone were compared with patients receiving combined therapy with epinephrine and hemoclip, and re-bleeding rates were reported as 21% in patients receiving monotherapy and as 3.8% in patients receiving combined therapy. The need for emergency surgery was observed only in the group treated with epinephrine and was found to be 9% (29). In a review, re-bleeding and the need for surgery were observed less in patients who received endoscopic combined therapy than patients who received endoscopic monotherapy (30). Guagliemi et al. reported the re-bleeding rates in patients with upper GIS bleeding who were provided hemostasis with epinephrine and sclerosing agents as 23.6% for Forrest 1a, as 19% for Forrest 1b, and as 19.5% for Forrest 2a (20). In the present study, however, re-bleeding rates were 28% (4/14) for Forrest 1a ulcer, 16% (10/62) for Forrest 1b ulcer, and 7.4% (2/27) for Forrest 2a ulcer and the re-bleeding rate of the overall series (group 1+2+3) was determined as 15.5% (16/103).

When the re-bleeding rates in the study were compared with other hemostatic methods except for epinephrine, these rates were found to be higher in patients with Forrest 1a and 1b ulcers than in the literature, but they were found to be similar to those in the literature when compared with the results of the studies where epinephrine injection treatment was administered alone. Re-bleeding rates were lower in patients...
with Forrest 2a ulcers when compared to the results of the studies in the literature where epinephrine injections were administered alone, but these rates were found to be similar with the results obtained when compared with other non-epinephrine hemostasis methods. The re-bleeding rates of the general series of the present study (15.5%) were found to be consistent with the literature.

When the re-bleeding rates in patients with Forrest 1a and Forrest 1b ulcers were compared with the rates of re-bleeding after combined treatment, these rates were found to be higher than those in the literature. In patients with Forrest 2a ulcer, however, when the rates of re-bleeding were compared with the rates of re-bleeding in combined treatment, they were found to be similar to those in the literature. In the present study, the rate of patients who needed urgent surgery was 5.7% and this rate was lower than the rate of surgical need in patients who underwent monotherapy in the literature, while it was similar to the rate of surgery need in studies where the combined therapy was administered.

The American Society for Gastrointestinal Endoscopy and European Society for Gastrointestinal Endoscopy guidelines recommend the administration of endoscopic treatment for classes Forrest 1a and 1b with bleeding ulcers and ulcers with bleeding but not visible vessels in class Forrest 2a (11, 22). In the guidelines, the administration of a second hemostasis modality with ESGE epinephrine injection is recommended, whereas epinephrine injection alone is not recommended in the classes Forrest 1a and 1b. In Forrest 2a, however, while mechanical, thermal or sclerosing agents were recommended to be administered as monotherapy or in combination with epinephrine injection, epinephrine injection alone was not recommended (11).

CONCLUSION

In conclusion, although adrenaline injection as an endoscopic treatment in GIS bleeding has a high success rate in achieving primary hemostasis, as discussed above, re-bleeding rates are higher than those in combined therapies. Therefore, it is thought that endoscopic combined treatment should be applied especially in patients with Forrest 1a and 1b bleeding ulcers, whereas in Forrest 2a ulcer patients, because of both the high rate of primary hemostasis and low rate of re-bleeding according to the results of the present study, the treatment of adrenalin injection alone can be used alone like other hemostasis modalities.
